Received 9 November 2001; received in revised form 20 June 2003; accepted 26 June 2003

## Abstract

This paper aims to present a review of recent as well as classic image registration methods. Image registration is the process of overlaying images (two or more) of the same scene taken at different times, from different viewpoints, and/or by different sensors. The registration geometrically align two images (the *reference* and *sensed* images). The reviewed approaches are classified according to their nature (*area-based* and *feature-based*) and according to four basic steps of image registration procedure: *feature detection*, *feature matching*, *mapping function design*, and *image transformation and resampling*. Main contributions, advantages, and drawbacks of the methods are mentioned in the paper. Problematic issues of image registration and outlook for the future research are discussed too. The major goal of the paper is to provide a comprehensive reference source for the researchers involved in image registration, regardless of particular application areas.

**Keywords:** Image registration; Feature detection; Feature matching; Mapping function; Resampling

## 1. Introduction

Image registration is the process of overlaying two or more images of the same scene taken at different times, from different viewpoints, and/or by different sensors. It geometrically aligns two images—the reference and sensed images. The present differences between images are introduced due to different imaging conditions. Image registration is a crucial step in all image analysis tasks in which the final information is gained from the combination of various data sources like in image fusion, change detection, and multichannel image restoration. Typically, registration is required in remote sensing (multispectral classification, environmental monitoring, change detection, image mosaicing, weather forecasting, creating super-resolution images, integrating information into geographic information systems (GIS)), in medicine (combining computer tomography (CT) and NMR data to obtain more complete information about the patient, monitoring tumor growth, treatment verification, comparison of the patient's data with anatomical atlases), in cartography (map updating), and in computer vision

(target localization, automatic quality control), to name a few.

During the last decades, image acquisition devices have undergone rapid development and growing amount and diversity of obtained images invoked the research on automatic image registration. A comprehensive survey of image registration methods was published in 1992 by Brown [26]. The intention of our article is to cover relevant approaches introduced later and in this way map the current development of registration techniques. According to the database of the Institute of Scientific Information (ISI), in the last 10 years more than 1000 papers were published on the topic of image registration. Methods published before 1992 that became classic or introduced key ideas, which are still in use, are included as well to retain the continuity and to give complete view of image registration research. We do not contemplate to go into details of particular algorithms or describe results of comparative experiments, rather we want to summarize main approaches and point out interesting parts of the registration methods.

In Section 2 various aspects and problems of image registration will be discussed. Both area-based and feature-based approaches to feature selection are described in Section 3. Section 4 reviews the existing algorithms for feature matching. Methods for mapping function design are given in Section 5. Finally, Section 6 surveys main

techniques for image transformation and resampling. Evaluation of the image registration accuracy is covered in Section 7. Section 8 concludes main trends in the research on registration methods and offers the outlook for the future.

## 2. Image registration methodology

Image registration, as it was mentioned above, is widely used in remote sensing, medical imaging, computer vision etc. In general, its applications can be divided into four main groups according to the manner of the image acquisition:

*Different viewpoints (multiview analysis).* Images of the same scene are acquired from different viewpoints. The aim is to gain larger a 2D view or a 3D representation of the scanned scene.

Examples of applications: Remote sensing—mosaicing of images of the surveyed area. Computer vision—shape recovery (shape from stereo).

*Different times (multitemporal analysis).* Images of the same scene are acquired at different times, often on regular basis, and possibly under different conditions. The aim is to find and evaluate changes in the scene which appeared between the consecutive image acquisitions.

Examples of applications: Remote sensing—monitoring of global land usage, landscape planning. Computer vision—automatic change detection for security monitoring, motion tracking. Medical imaging—monitoring of the healing therapy, monitoring of the tumor evolution.

*Different sensors (multimodal analysis).* Images of the same scene are acquired by different sensors. The aim is to integrate the information obtained from different source streams to gain more complex and detailed scene representation.

Examples of applications: Remote sensing—fusion of information from sensors with different characteristics like panchromatic images, offering better spatial resolution, color/multispectral images with better spectral resolution, or radar images independent of cloud cover and solar illumination. Medical imaging—combination of sensors recording the anatomical body structure like magnetic resonance image (MRI), ultrasound or CT with sensors monitoring functional and metabolic body activities like positron emission tomography (PET), single photon emission computed tomography (SPECT) or magnetic resonance spectroscopy (MRS). Results can be applied, for instance, in radiotherapy and nuclear medicine.

*Scene to model registration.* Images of a scene and a model of the scene are registered. The model can be a computer representation of the scene, for instance maps or digital elevation models (DEM) in GIS, another scene with similar content (another patient), ‘average’ specimen, etc. The aim is to localize the acquired image in the scene/model and/or to compare them.

Examples of applications: Remote sensing—registration of aerial or satellite data into maps or other GIS layers.

Computer vision—target template matching with real-time images, automatic quality inspection. Medical imaging—comparison of the patient’s image with digital anatomical atlases, specimen classification.

Due to the diversity of images to be registered and due to various types of degradations it is impossible to design a universal method applicable to all registration tasks. Every method should take into account not only the assumed type of geometric deformation between the images but also radiometric deformations and noise corruption, required registration accuracy and application-dependent data characteristics.

Nevertheless, the majority of the registration methods consists of the following four steps (see Fig. 1):

- *Feature detection.* Salient and distinctive objects (closed-boundary regions, edges, contours, line intersections, corners, etc.) are manually or, preferably, automatically detected. For further processing, these features can be represented by their point representatives (centers of gravity, line endings, distinctive points), which are called control points (CPs) in the literature.
- *Feature matching.* In this step, the correspondence between the features detected in the sensed image and those detected in the reference image is established. Various feature descriptors and similarity measures along with spatial relationships among the features are used for that purpose.
- *Transform model estimation.* The type and parameters of the so-called mapping functions, aligning the sensed image with the reference image, are estimated. The parameters of the mapping functions are computed by means of the established feature correspondence.
- *Image resampling and transformation.* The sensed image is transformed by means of the mapping functions. Image values in non-integer coordinates are computed by the appropriate interpolation technique.

The implementation of each registration step has its typical problems. First, we have to decide what kind of features is appropriate for the given task. The features should be distinctive objects, which are frequently spread over the images and which are easily detectable. Usually, the physical interpretability of the features is demanded. The detected feature sets in the reference and sensed images must have enough common elements, even in situations when the images do not cover exactly the same scene or when there are object occlusions or other unexpected changes. The detection methods should have good localization accuracy and should not be sensitive to the assumed image degradation. In an ideal case, the algorithm should be able to detect the same features in all projections of the scene regardless of the particular image deformation.

In the feature matching step, problems caused by an incorrect feature detection or by image degradations can

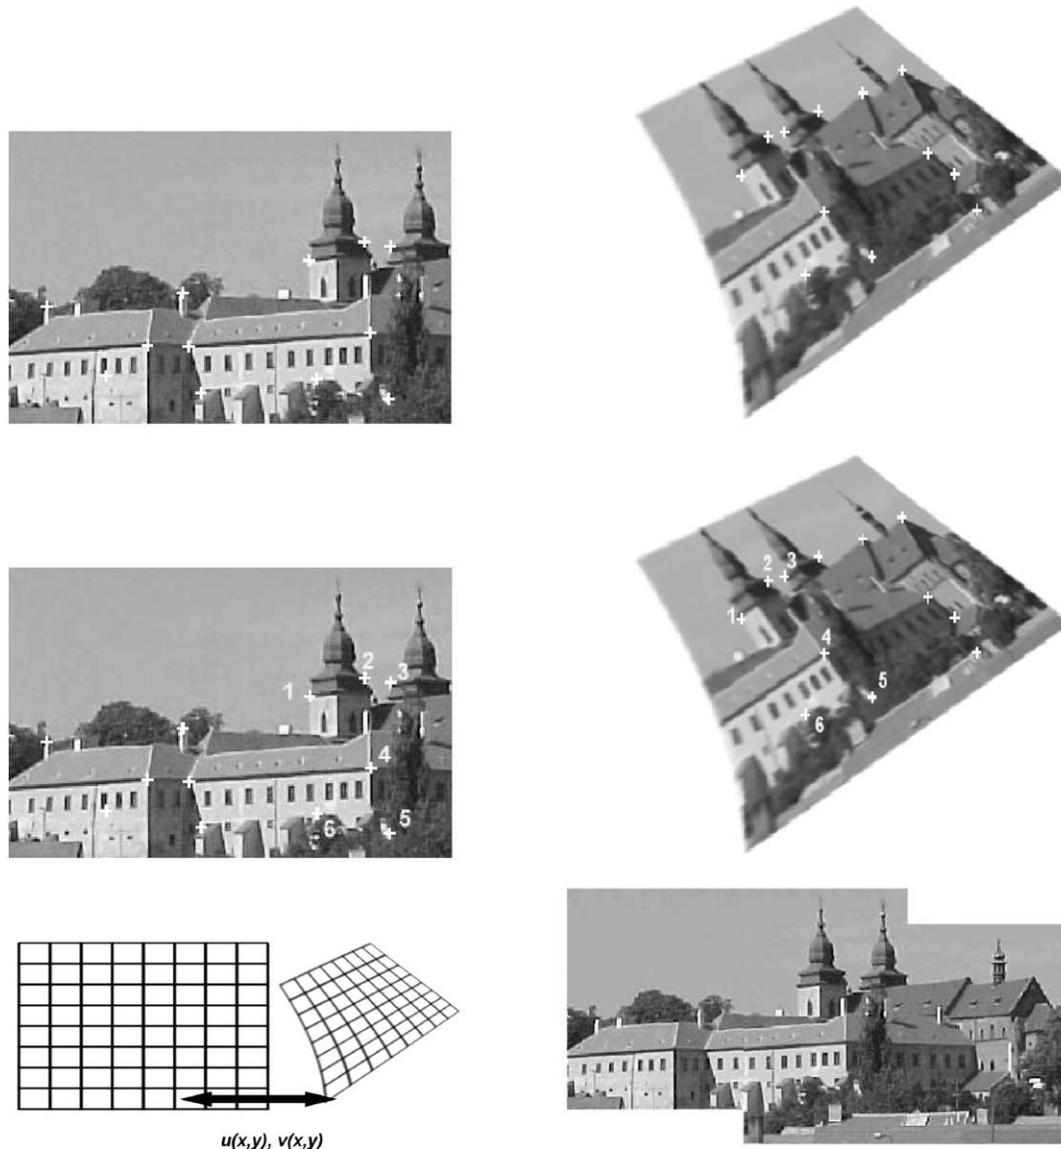

Fig. 1. Four steps of image registration: top row—feature detection (corners were used as the features in this case). Middle row—feature matching by invariant descriptors (the corresponding pairs are marked by numbers). Bottom left—transform model estimation exploiting the established correspondence. Bottom right—image resampling and transformation using appropriate interpolation technique.

arise. Physically corresponding features can be dissimilar due to the different imaging conditions and/or due to the different spectral sensitivity of the sensors. The choice of the feature description and similarity measure has to consider these factors. The feature descriptors should be invariant to the assumed degradations. Simultaneously, they have to be discriminable enough to be able to distinguish among different features as well as sufficiently stable so as not to be influenced by slight unexpected feature variations and noise. The matching algorithm in the space of invariants should be robust and efficient. Single features without corresponding counterparts in the other image should not affect its performance.

The type of the mapping functions should be chosen according to the a priori known information

about the acquisition process and expected image degradations. If no a priori information is available, the model should be flexible and general enough to handle all possible degradations which might appear. The accuracy of the feature detection method, the reliability of feature correspondence estimation, and the acceptable approximation error need to be considered too. Moreover, the decision about which differences between images have to be removed by registration has to be done. It is desirable not to remove the differences we are searching for if the aim is a change detection. This issue is very important and extremely difficult.

Finally, the choice of the appropriate type of resampling technique depends on the trade-off between the demanded accuracy of the interpolation and the computational

complexity. The nearest-neighbor or bilinear interpolation are sufficient in most cases; however, some applications require more precise methods.

Because of its importance in various application areas as well as because of its complicated nature, image registration has been the topic of much recent research. The historically first survey paper [64] covers mainly the methods based on image correlation. Probably the most exhaustive review of the general-purpose image registration methods is in Ref. [26]. Registration techniques applied particularly in medical imaging are summarized in Refs. [86,111,123,195]. In Ref. [9] the surface based registration methods in medical imaging are reviewed. Volume-based registration is reviewed in Ref. [40]. The registration methods applied mainly in remote sensing are described and evaluated in [59,81,106]. Big evaluation project of different registration methods was run in Vanderbilt university [206].

Registration methods can be categorized with respect to various criteria. The ones usually used are the application area, dimensionality of data, type and complexity of assumed image deformations, computational cost, and the essential ideas of the registration algorithm. Here, the classification according to the essential ideas is chosen, considering the decomposition of the registration into the described four steps. The techniques exceeding this four-step framework are covered according to their major contribution.

### 3. Feature detection

Formerly, the features were objects manually selected by an expert. During an automation of this registration step, two main approaches to feature understanding have been formed.

#### 3.1. Area-based methods

Area-based methods put emphasis rather on the feature matching step than on their detection. No features are detected in these approaches so the first step of image registration is omitted. The methods belonging to this class will be covered in sections corresponding to the other registration steps.

#### 3.2. Feature-based methods

The second approach is based on the extraction of salient structures—features—in the images. Significant regions (forests, lakes, fields), lines (region boundaries, coastlines, roads, rivers) or points (region corners, line intersections, points on curves with high curvature) are understood as features here. They should be distinct, spread all over the image and efficiently detectable in both images. They are expected to be stable in time to stay at fixed positions during the whole experiment.

The comparability of feature sets in the sensed and reference images is assured by the invariance and accuracy of the feature detector and by the overlap criterion. In other words, the number of common elements of the detected sets of features should be sufficiently high, regardless of the change of image geometry, radiometric conditions, presence of additive noise, and of changes in the scanned scene. The ‘remarkableness’ of the features is implied by their definition. In contrast to the area-based methods, the feature-based ones do not work directly with image intensity values. The features represent information on higher level. This property makes feature-based methods suitable for situations when illumination changes are expected or multisensor analysis is demanded.

*Region features.* The region-like features can be the projections of general high contrast closed-boundary regions of an appropriate size [54,72], water reservoirs, and lakes [71,88], buildings [92], forests [165], urban areas [161] or shadows [24]. The general criterion of closed-boundary regions is prevalent. The regions are often represented by their centers of gravity, which are invariant with respect to rotation, scaling, and skewing and stable under random noise and gray level variation.

Region features are detected by means of segmentation methods [137]. The accuracy of the segmentation can significantly influence the resulting registration. Goshtasby et al. [72] proposed a refinement of the segmentation process to improve the registration quality. The segmentation of the image was done iteratively together with the registration; in every iteration, the rough estimation of the object correspondence was used to tune the segmentation parameters. They claimed the subpixel accuracy of registration could be achieved.

Recently, selection of region features invariant with respect to change of scale caught attention. Alhichri and Kamel [2] proposed the idea of virtual circles, using distance transform. Affinely invariant neighborhoods were described in [194], based on Harris corner detector [135] and edges (curved or straight) going through detected corners. Different approach to this problem using Maximally Stable Extremal Regions based on homogeneity of image intensities was presented by Matas et al. [127].

*Line features.* The line features can be the representations of general line segments [92,132,205], object contours [36,74,112], coastal lines, [124,168], roads [114] or elongated anatomic structures [202] in medical imaging. Line correspondence is usually expressed by pairs of line ends or middle points.

Standard edge detection methods, like Canny detector [28] or a detector based on the Laplacian of Gaussian [126], are employed for the line feature detection. The survey of existing edge detection method together with their evaluation can be found in [222]. Li et al. [112] proposed to exploit the already detected features in the reference image (optical data) for the detection of lines in the sensed images (SAR images with speckle noise, which is a typical

degradation present in this type of data). They applied elastic contour extraction. The comparison of different operators for the feature edge detection and the ridge detection in multimodal medical images is presented by Maintz et al. [121,122].

*Point features.* The point features group consists of methods working with line intersections [175,198], road crossings [79,161], centroids of water regions, oil and gas pads [190], high variance points [45], local curvature discontinuities detected using the Gabor wavelets [125, 219], inflection points of curves [3,11], local extrema of wavelet transform [58,90], the most distinctive points with respect to a specified measure of similarity [115], and corners [20,92,204].

The core algorithms of feature detectors in most cases follow the definitions of the ‘point’ as line intersection, centroid of closed-boundary region or local modulus maxima of the wavelet transform. Corners form specific class of features, because ‘to-be-a-corner’ property is hard to define mathematically (intuitively, corners are understood as points of high curvature on the region boundaries). Much effort has been spent in developing precise, robust, and fast method for corner detection. A survey of corner detectors can be found in Refs. [155,172,220] and the most up-to-date and exhaustive in Ref. [156]. The latter also analyzes localization properties of the detectors. Corners are widely used as CPs mainly because of their invariance to imaging geometry and because they are well perceived by a human observer.

Kitchen and Rosenfeld [101] proposed to exploit the second-order partial derivatives of the image function for corner detection. Dreschler and Nagel [43] searched for the local extrema of the Gaussian curvature. However, corner detectors based on the second-order derivatives of the image function are sensitive to noise. Thus Förstner [62] developed a more robust, although time consuming, corner detector, which is based on the first-order derivatives only. The reputable Harris detector (also referred to as the Plessey detector) [135] is in fact its inverse. The application of the Förstner detector is described in Ref. [107], where it is used for the registration of dental implants images.

More intuitive approach was chosen by Smith and Brady [173] in their robust SUSAN method. As the criterion they used the size of the area of the same color as that of the central pixel. Trajkovic and Hedley [192] designed their operator using the idea that the change of the image intensity at the corners should be high in all directions. Recently, Zitová et al. [224] proposed a parametric corner detector, which does not employ any derivatives and which was designed to handle blurred and noisy data. Rohr et al. designed corner detectors, even for 3D data, allowing user interaction [158].

The number of detected points can be very high, which increases the computational time necessary for the registration. Several authors proposed methods for an efficient selection of a subset of points (better than random) which

does not degrade the quality of the resulting registration. Goshtasby [71] used only points belonging to a convex hull of the whole set. Lavine [104] proposed to use points forming the minimum spanning trees of sets. Ehlers [45] merged points into ‘clumps’—large dense clusters.

### 3.3. Summary

To summarize, the use of feature-based methods is recommended if the images contain enough distinctive and easily detectable objects. This is usually the case of applications in remote sensing and computer vision. The typical images contain a lot of details (towns, rivers, roads, forests, room facilities, etc). On the other hand, medical images are not so rich in such details and thus area-based methods are usually employed here. Sometimes, the lack of distinctive objects in medical images is solved by the interactive selection done by an expert or by introducing extrinsic features, rigidly positioned with respect to the patient (skin markers, screw markers, dental adapters, etc.) [123]. The applicability of area-based and feature-based methods for images with various contrast and sharpness is analyzed in Ref. [151]. Recently, registration methods using simultaneously both area-based and feature-based approaches have started to appear [85].

## 4. Feature matching

The detected features in the reference and sensed images can be matched by means of the image intensity values in their close neighborhoods, the feature spatial distribution, or the feature symbolic description. Some methods, while looking for the feature correspondence, simultaneously estimate the parameters of mapping functions and thus merge the second and third registration steps.

In the following paragraphs, the two major categories (area-based and feature-based methods, respectively), are retained and further classified into subcategories according to the basic ideas of the matching methods.

### 4.1. Area-based methods

Area-based methods, sometimes called correlation-like methods or template matching [59] merge the feature detection step with the matching part. These methods deal with the images without attempting to detect salient objects. Windows of predefined size or even entire images are used for the correspondence estimation during the second registration step, [4,12,145].

The limitations of the area-based methods originate in their basic idea. Firstly, the rectangular window, which is most often used, suits the registration of images which locally differ only by a translation. If images are deformed by more complex transformations, this type of the window is not able to cover the same parts of the scene in

the reference and sensed images (the rectangle can be transformed to some other shape). Several authors proposed to use circular shape of the window for mutually rotated images. However, the comparability of such simple-shaped windows is violated too if more complicated geometric deformations (similarity, perspective transforms, etc.) are present between images.

Another disadvantage of the area-based methods refers to the ‘remarkableness’ of the window content. There is high probability that a window containing a smooth area without any prominent details will be matched incorrectly with other smooth areas in the reference image due to its non-saliency. The features for registration should be preferably detected in distinctive parts of the image. Windows, whose selection is often not based on their content evaluation, may not have this property.

Classical area-based methods like cross-correlation (CC) exploit for matching directly image intensities, without any structural analysis. Consequently, they are sensitive to the intensity changes, introduced for instance by noise, varying illumination, and/or by using different sensor types.

#### 4.1.1. Correlation-like methods

The classical representative of the area-based methods is the normalized CC and its modifications [146].

$$CC(i, j) = \frac{\sum_w (W - E(W))(I_{(i,j)} - E(I_{(i,j)}))}{\sqrt{\sum_w (W - E(W))^2} \sqrt{\sum_{I_{(i,j)}} (I_{(i,j)} - E(I_{(i,j)}))^2}}$$

This measure of similarity is computed for window pairs from the sensed and reference images and its maximum is searched. The window pairs for which the maximum is achieved are set as the corresponding ones (see Fig. 2). If the subpixel accuracy of the registration is demanded, the interpolation of the CC measure values needs to be used. Although the CC based registration can exactly align mutually translated images only, it can also be successfully applied when slight rotation and scaling are present.

There are generalized versions of CC for geometrically more deformed images. They compute the CC for each assumed geometric transformation of the sensed image window [83] and are able to handle even more complicated geometric deformations than the translation—usually the similarity transform. Berthilsson [17] tried to register in this manner even affinely deformed images and Simper [170] proposed to use a divide and conquer system and the CC technique for registering images differing by perspective changes as well as changes due to the lens imperfections. The computational load, however, grows very fast with the increase of the transformation complexity. In case the images/objects to be registered are partially occluded the extended CC method based on increment sign correlation [98] can be applied [99].

Similar to the CC methods is the sequential similarity detection algorithm (SSDA) [12]. It uses the sequential search approach and a computationally simpler distance

measure than the CC. It accumulates the sum of absolute differences of the image intensity values (matrix  $l_1$  norm) and applies the threshold criterion—if the accumulated sum exceeds the given threshold, the candidate pair of windows from the reference and sensed images is rejected and the next pair is tested. The method is likely to be less accurate than the CC but it is faster. Sum of squared differences similarity measure was used in Ref. [211] for iterative estimation of perspective deformation using piecewise affine estimates for image decomposed to small patches.

Recently big interest in the area of multimodal registration has been paid to the correlation ratio based methods. In opposite to classical CC, this similarity measure can handle intensity differences between images due to the usage of different sensors—multimodal images. It supposes that intensity dependence can be represented by some function. Comparison of this approach to several other algorithms developed for multimodal data can be found in Ref. [154]. In case of noisy images with certain characteristic (fixed-pattern noise), projection-based registration [27], working with accumulated image rows and columns, respectively, outperforms classical CC.

Huttenlocher et al. [95] proposed a method working with other type of similarity measure. They registered binary images (the output of an edge detector) transformed by translation or translation plus rotation, by means of the Hausdorff distance (HD). They compared the HD based algorithm with the CC. Especially on images with perturbed pixel locations, which are problematic for CC, HD outperforms the CC.

Two main drawbacks of the correlation-like methods are the flatness of the similarity measure maxima (due to the self-similarity of the images) and high computational complexity. The maximum can be sharpened by preprocessing or by using the edge or vector correlation. Pratt [145] applied, prior to the registration, image filtering to improve the CC performance on noisy or highly correlated images. Van Wie [196] and Anuta [6] employed the edge-based correlation, which is computed on the edges extracted from the images rather than on the original images themselves. In this way, the method is less sensitive to intensity differences between the reference and sensed images, too. Extension of this approach, called vector-based correlation, computes the similarity measures using various representations of the window.

Despite the limitations mentioned above, the correlation-like registration methods are still often in use, particularly thanks to their easy hardware implementation, which makes them useful for real-time applications.

#### 4.1.2. Fourier methods

If an acceleration of the computational speed is needed or if the images were acquired under varying conditions or they are corrupted by frequency-dependent noise, then Fourier methods are preferred rather than the correlation-like methods. They exploit the Fourier representation of

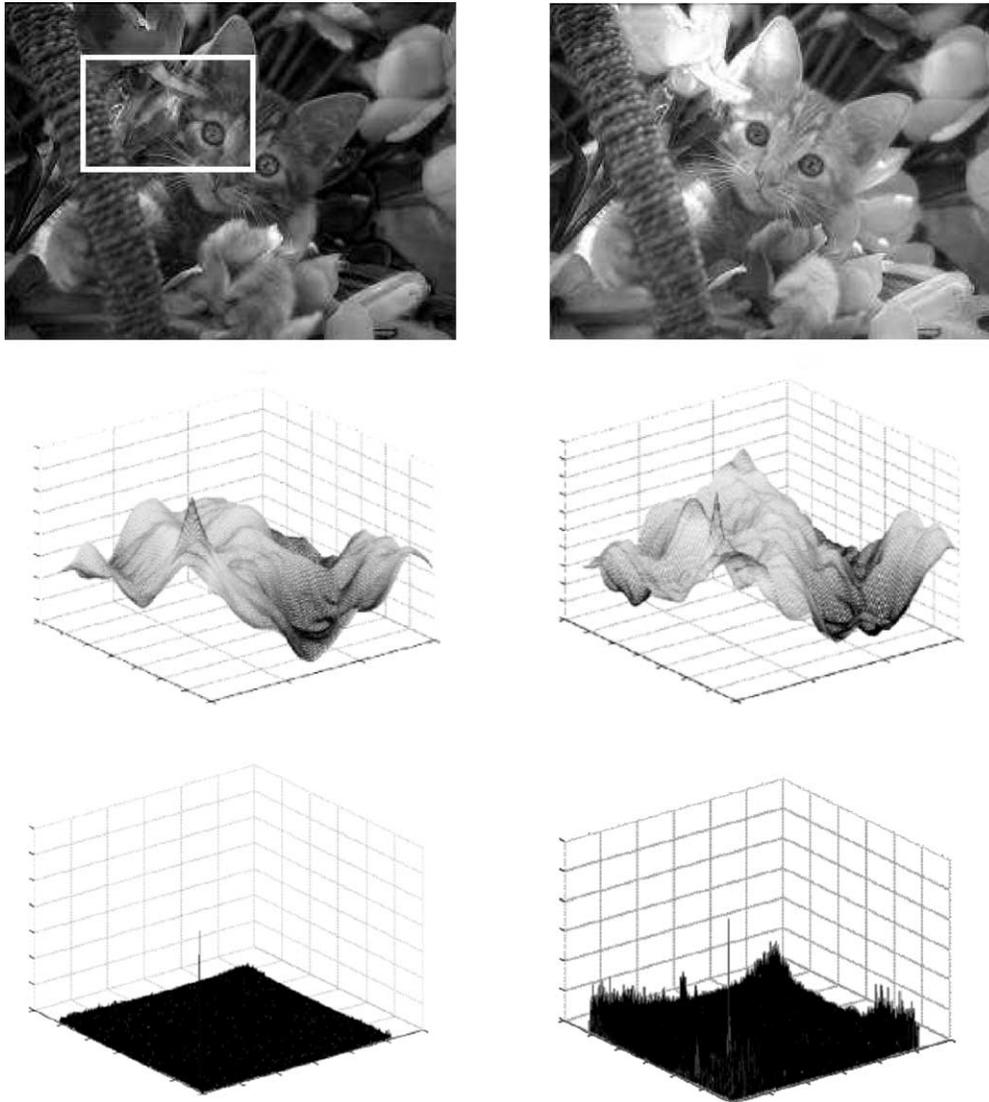

Fig. 2. Area-based matching methods: registration of small template to the whole image using normalized cross-correlation (middle row) and phase correlation (bottom row). The maxima identify the matching positions. The template is of the same spectral band as the reference image (the graphs on the left depict red-red channel matching) and of different spectral band (the graphs on the right demonstrate red-blue channel matching). In a general case the normalized cross-correlation could fail in case of multimodal data.

the images in the frequency domain. The phase correlation method is based on the Fourier Shift Theorem [23] and was originally proposed for the registration of translated images. It computes the cross-power spectrum of the sensed and reference images and looks for the location of the peak in its inverse (see Fig. 2).

$$\frac{\mathcal{F}(f)\mathcal{F}(g)^*}{|\mathcal{F}(f)\mathcal{F}(g)^*|} = e^{2\pi i(ux_0+vy_0)}$$

The method shows strong robustness against the correlated and frequency dependent noise and non-uniform, time varying illumination disturbances. The computational time savings are more significant if the images, which are to be registered, are large.

De Castro and Morandi [29] introduced an extension of the phase correlation for additional rotation transform.

If the change of image scale is present too, the images can be registered using the combination of polar-log mapping of the spectral magnitude (which corresponds to Fourier–Mellin transform) and the phase correlation [31, 150] or cepstrum filter [107]. The applications of the extended algorithm in remote sensing (SPOT images) and medical imaging (MR images) are described in Ref. [31]. The testing of the accuracy of the method in simulated conditions (registration of deformed and noisy images of ocular fundus) was performed with satisfying results [34]. Affinely distorted images were registered by means of phase correlation and log-polar mapping in Ref. [210]. Application of phase correlation in 3D is described in Ref. [119]. Another application exploiting the Fourier transform is described in Ref. [6]. The authors proposed to compute the correlation in frequency domain. This

method can handle multimodal images when applied to the edge representations instead of the original graylevel images. Extension of phase correlation to subpixel registration by means of the analytic expression of phase correlation on down sampled images was introduced by Foroosh et al. [61].

#### 4.1.3. Mutual information methods

The mutual information (MI) methods are the last group of the area-based methods to be reviewed here. They have appeared recently and represent the leading technique in multimodal registration. Registration of multimodal images is the difficult task, but often necessary to solve, especially in medical imaging. The comparison of anatomical and functional images of the patient's body can lead to a diagnosis, which would be impossible to gain otherwise. Remote sensing often makes use of the exploitation of more sensor types, too.

The MI, originating from the information theory, is a measure of statistical dependency between two data sets and it is particularly suitable for registration of images from

different modalities. MI between two random variables  $X$  and  $Y$  is given by

$$MI(X, Y) = H(Y) - H(Y|X) = H(X) + H(Y) - H(X, Y),$$

where  $H(X) = -E_X(\log(P(X)))$  represents entropy of random variable and  $P(X)$  is the probability distribution of  $X$ . The method is based on the maximization of MI (Fig. 3) Often the speed up of the registration is implemented, exploiting the coarse-to-fine resolution strategy (the pyramidal approach).

One of the first articles proposing this technique is Viola and Wells [201]. The authors described the application of MI for the registration by magnetic resonance images as well as for the 3D object model matching to the real scene. MI was maximized using the gradient descent optimization method. Thévenaz and Unser [186–188] tried to combine various approaches, solving individual steps of MI registration. They employed the Parzen window for the joint probability computation and the Jeeves method [187] or the Marquardt–Levenberg method [186] to maximize the MI. To speed up the computation, they used spline pyramids

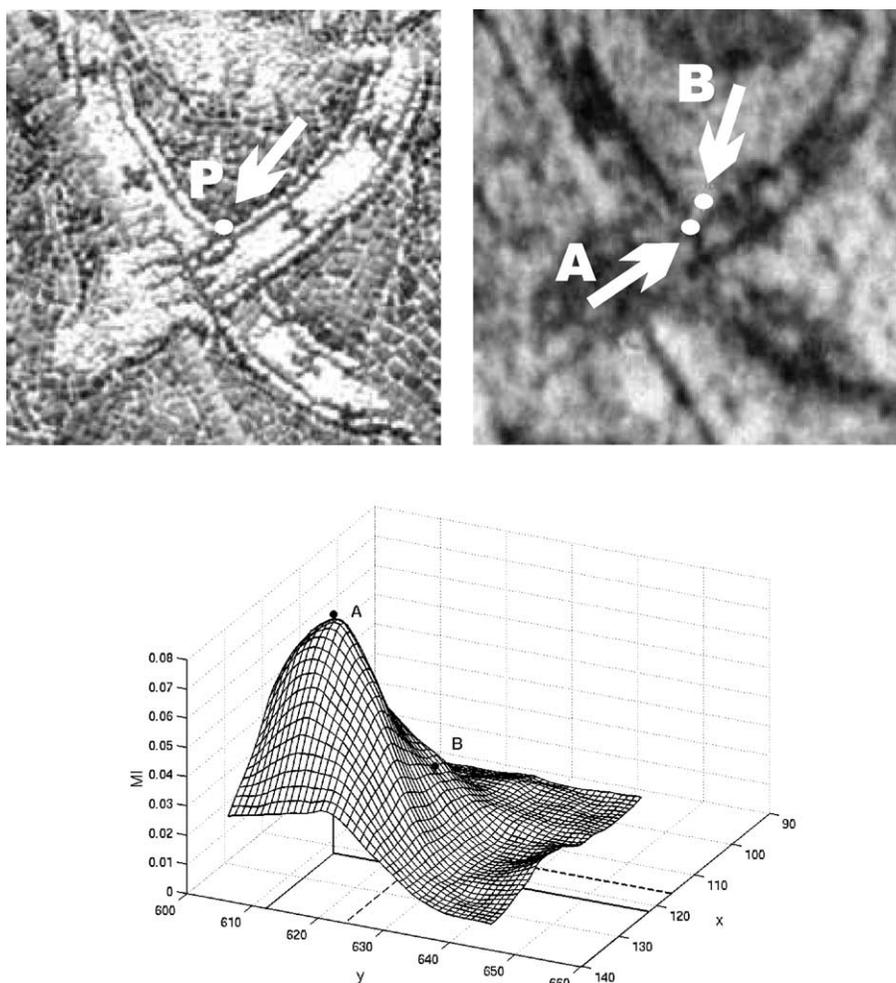

Fig. 3. Mutual information: MI criterion (bottom row) computed in the neighborhood of point P between new and old photographs of the mosaic (top row). Maximum of MI shows the correct matching position (point A). Point B indicates the false matching position selected previously by the human operator. The mistake was caused by poor image quality and by complex nature of the image degradations.

[188]. Ritter et al. [152] used hierarchical search strategy together with simulated annealing to find the maximum of the MI. Studholme et al. [177] compared three similar measures of information dependency—the joint entropy, the MI, and the normalized MI (a new idea, claimed to outperform the others). They applied discrete histogram estimates of the joint probability distribution instead of application of the Parzen window used in previous work. Maximization was achieved by using a multiresolution hill climbing algorithm. They registered MR-CT and MR-PET images of a human brain. Maes et al. [120] optimized the MI by means of the Brent's method and the Powell's multidimensional direction set method to register MR, CT, and PET images of a human brain that differ by similarity transform. MI applied to breast MR images is described in Ref. [162]. The authors proposed to model the global deformation present between the images by a combination of the affine transformations and the spline-based free form deformation. Likar and Pernus [116] studied the performance of different methods for the joint probability estimation in registration of muscle fibre images. The comparison of the basic MI registration with the version employing the coarse-to-fine speed up was done in Ref. [143]. The comparison of MI to six other registration methods including the normalized CC and the gradient correlation is described in Ref. [142]. The relation of MI to other area-based similarity (correlation coefficients, correlation ratio) measures is described in Ref. [153] using the formulation of maximum likelihood estimation problem.

The above mentioned MI methods work with the entire image data and directly with image intensities. Rangarajan et al. [149] applied MI on extracted features (points of the area borders), but this approach is still rare. Similar to MI, coming from the theory of information, is similarity measure based on cross-entropy [221].

#### 4.1.4. Optimization methods

Finding the minimum of dissimilarity measure (penalty function) or the maximum of similarity measure is a multidimensional optimization problem, where the number of dimensions corresponds to the degrees of freedom of the expected geometrical transformation. The only method yielding global extreme solution is an exhaustive search over the entire image. Although it is computationally demanding, it is often used if only translations are to be estimated.

In case of transformations with more degrees of freedom or in case of more complex similarity measures, sophisticated optimization algorithms are required, which help to localize the maxima or minima, respectively. The application of Gauss–Newton numerical minimization algorithm for minimizing the sum of squared differences is described in Ref. [166], where the projective geometric deformation was used. In Ref. [201] maxima of MI was found using the gradient descent optimization method. Levenberg–Marquardt optimization method was applied in Ref. [164] to

minimize the variance in intensities of corresponding pixels. The images were registered by means of the projective transformation model plus the lens distortion model. The combination of the Levenberg–Marquardt method and the sum of the squared differences metric is described in Ref. [185]. Similarly, Wolberg and Zokai [211] used this combination for registering of perspectively deformed images. The Powell's multidimensional direction set method [96] is applied in Maes et al. [120]. Starink and Backer [174] tried to minimize a dissimilarity measure defined on point pairs by means of simulated annealing. Another optimization method, suited for multimodal data registration was introduced in Ref. [97] and its applicability was proved in combination with MI and correlation ratio. Again, the optimization methods can be speeded up by the pyramidal approach.

There should be noted one thing with respect to these optimization methods. Sometimes next to the dissimilarity measure term the formula to be minimized contains as well so-called regularization or penalty term, which interconnects the transformation and data to be transformed [82]. These two terms together form the cost function (energy) associated with the registration and the aim of the optimization methods is to minimize it. In literature such methods can be referred to as *energy minimization methods*. The regularization term is usually omitted in case of rigid body transforms, but in non-rigid transformations such as elastic or fluid registration methods, described more in detail in Section 5, is present.

#### 4.2. Feature-based methods

We assume that two sets of features in the reference and sensed images represented by the CPs (points themselves, end points or centers of line features, centers of gravity of regions, etc.) have been detected. The aim is to find the pairwise correspondence between them using their spatial relations or various descriptors of features.

##### 4.2.1. Methods using spatial relations

Methods based primarily on the spatial relations among the features are usually applied if detected features are ambiguous or if their neighborhoods are locally distorted. The information about the distance between the CPs and about their spatial distribution is exploited.

Goshtasby in Ref. [71] described the registration based on the graph matching algorithm. He was evaluating the number of features in the sensed image that, after the particular transformation, fall within a given range next to the features in the reference image. The transformation parameters with the highest score were then set as a valid estimate.

Clustering technique, presented by Stockman et al. [175], tries to match points connected by abstract edges or line segments. The assumed geometrical model is the similarity transform. For every pair of CPs from both the reference and

sensed images, the parameters of the transformation which maps the points on each other are computed and represented as a point in the space of transform parameters. The parameters of transformations that closely map the highest number of features tend to form a cluster, while mismatches fill the parameter space randomly. The cluster is detected and its centroid is assumed to represent the most probable vector of matching parameters. Mapping function parameters are thus found simultaneously with the feature correspondence. Local errors do not influence globally the registration process. The clustering technique was implemented, for example, in Refs. [30,72].

Barrow et al. [14] introduced the chamfer matching for image registration. Line features detected in images are matched by means of the minimalization of the generalized distance between them. Borgefors [22] proposed an

improved version, where better measure of correspondence—the sequential distance transform together with the root mean square average—was applied. The algorithm employs also the pyramidal speed-up.

Even that this overview does not intend to cover 3D registration methods, here the well-known Iterative Closest Point (ICP) algorithm, introduced by Besl and McKay [18] is mentioned, because it represents a key approach for registering 3D shapes (including free-form curves and surfaces).

#### 4.2.2. Methods using invariant descriptors

As an alternative to the methods exploiting the spatial relations, the correspondence of features can be estimated using their description, preferably invariant to the expected image deformation (see Fig. 4). The description

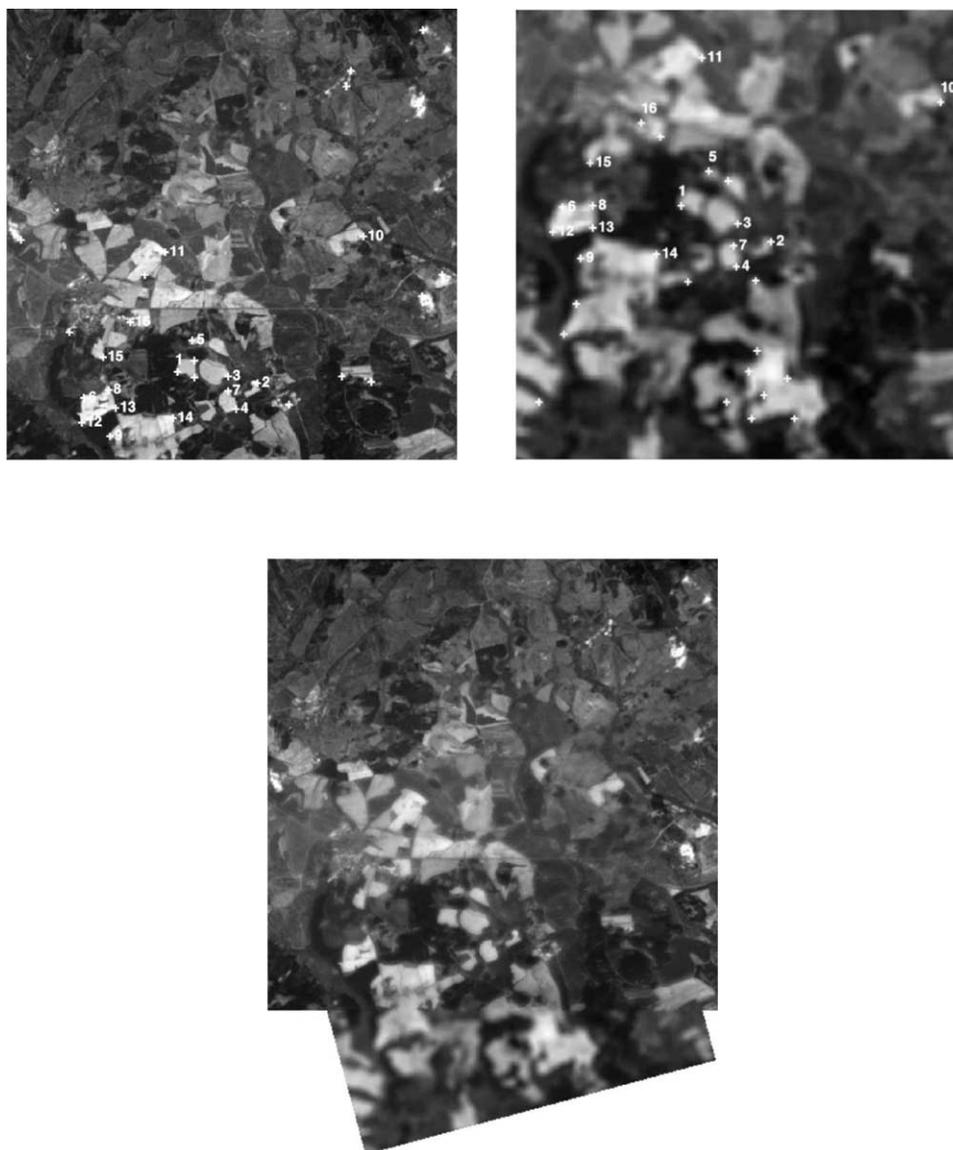

Fig. 4. Feature-based method using invariant descriptors: in these two satellite images, control points (corners) were matched using invariants based on complex moments [56]. The numbers identify corresponding CP's. The bottom image shows the registration result.

should fulfill several conditions. The most important ones are *invariance* (the descriptions of the corresponding features from the reference and sensed image have to be the same), *uniqueness* (two different features should have different descriptions), *stability* (the description of a feature which is slightly deformed in an unknown manner should be close to the description of the original feature), and *independence* (if the feature description is a vector, its elements should be functionally independent). However, usually not all these conditions have to (or can) be satisfied simultaneously and it is necessary to find an appropriate trade-off.

Features from the sensed and reference images with the most similar invariant descriptions are paired as the corresponding ones. The choice of the type of the invariant description depends on the feature characteristics and the assumed geometric deformation of the images. While searching for the best matching feature pairs in the space of feature descriptors, the minimum distance rule with thresholding is usually applied. If a more robust algorithm is needed, the matching likelihood coefficients [51], which can better handle questionable situations, can be an appropriate solution. Guest et al. proposed to select features according to the reliability of their possible matches [80].

The simplest feature description is the image intensity function itself, limited to the close neighborhood of the feature [1,107]. To estimate the feature correspondence, authors computed the CC on these neighborhoods. Other types of similarity measures can be used, too. Zheng and Chellapa make use of the correlation coefficients [219]. They assumed the similarity geometric deformation. In their approach, firstly the rotation between images was compensated by the estimation of the illuminant direction and then the coarse-to-fine correlation based registration was performed. In Ref. [223] the MI was used for the improvement of the feature correspondence.

The following references are examples of the intuitive descriptions, which usually do not fulfill some of the mentioned criteria of invariant descriptors. Sester et al. [165] proposed to describe forests, used as the region features, by elongation parameter, compactness, number of holes, and several characteristics of the minimum bounding rectangle. To register stars with a catalog, Murtagh [133] assigned to every point feature the description of the spatial distribution of other features lying around. Vujovic and Brzakovic in Ref. [202] represented every detected feature (elongated structure intersections) by its signature formed by the longest structure and angles between all other structures, participating in the intersection. Similarly, Zana [218] described each feature point by means of angles between relevant intersecting lines. Montesinos et al. [131] proposed to use differential descriptors of the image function in the neighborhood of the detected CPs. Yang and Cohen [216] used border triangles generated by object convex hull and computed on them affine geometric invariants.

Many authors used closed-boundary regions as the features. In principle, any invariant and discriminative enough shape descriptor can be employed in region matching. Peli [141] proposed simple and fast description by radial shape vector but the usage of this method is limited to star-shape regions only. A generalized shape description in a form of a binary matrix was proposed in Ref. [65,180]. In Ref. [72], the shape matrices were used for registration of rotated and scaled satellite images. In Ref. [112] a chain code representation of contours was proposed as the invariant description and a chain code correlation-like measure was used for finding the correspondence. Skea et al. [171] represented non-collinear triplets of CPs by the sphericity. Suk [178] proposed the invariant shape description of the regions represented by polygons and further developed this approach in Ref. [179].

A large group of methods uses moment-based invariants for description of closed-boundary region features. Considering the most often assumed deformations, Hu [93] introduced moment invariants to the similarity transform. Flusser and Suk derived the affine transform invariants [53] and used them successfully for registration of SPOT and Landsat images [54]. Holm [88] extracted closed boundary regions and proposed to represent them by their perimeter, area, compactness, moments, and moment invariants. Bhattacharya [20] suggested the application of complex moments. Brivio et al. [24] modeled shadow structures in mountain images by means of their inertia ellipses. The ellipses are here described by their area, inclination of the main axis and ellipticity. All these attributes are functions of moments. Li et al. [112] used first two Hu's moments as preselectors for matching of closed contours. The candidate matches were tested using the chain code representation of the contours. A similar method was described in Ref. [35], where the moment invariants are used together with the chain codes. Sato and Cipolla [163] computed directly, without correspondence estimation, the parameters of the present geometric deformations (an affine transform was expected) using the circular moments of distribution of the line features orientation. They combined moments and the scale-space representation of the images. Recently, Flusser and Suk [55] introduced a new class of moment invariants that are invariant to image blurring and demonstrated their performance in registering SPOT and AVHRR satellite images. Bentoutou et al. [16] registered mutually shifted and blurred digital subtraction angiography images using these invariants. Flusser et al. further developed this approach in Ref. [56] by introducing the combined blur-rotation invariants. In Ref. [52] they generalized the previous invariants to register 3D images.

Invariant combination of the basic geometric properties of features can form geometrically oriented descriptors. Govindu et al. [74] represented the extracted contours from possibly rotated images by the slopes of tangents in the contour points. They did not look for contour

correspondence, but only for the distributions of the proposed descriptors. By comparison of the corresponding distributions from the reference and sensed images the mutual image rotation can be estimated. They derived a similar type of descriptors for the affine transform, too. A detailed study of the practical aspects of the proposed method can be found in Ref. [73]. Wang and Chen [205] computed the histogram of line-length ratios and the histogram of angle differences of any two line segments in the reference and sensed images. They assumed the similarity transform. Griffin and Alexopoulos [77] used the ratio of the smallest enclosing circle radii, the difference of the locations of centroids of gravity, and the sorting of the neighbors lexicographically according to the angle with the  $x$  axis and the distance from the centroid. All these methods skip the step of finding the feature correspondence and establish directly the mapping function parameters.

Hsieh et al. [91] used the angle histogram computed on line feature points for the compensation of rotation difference. After the removal of the rotation difference, the feature point correspondence is found by means of CC. They compared their rotation compensation with the one described in Ref. [219].

Shekhar et al. [167] combined different types of features and their descriptors. They decomposed the present geometric deformation into elementary steps and then estimated transform parameters using the feature consensus—every type of feature descriptor votes for the corresponding value of the parameter. The value of the parameter which maximizes the number of votes over all descriptor types is then chosen.

Ventura et al. [200] described image features by various descriptors (ellipticity, angle, thinness, etc.) and represented relations among them by a multivalued logical tree (MVLTL). Then they compared the MVLTLs of the reference and sensed images to find the feature correspondence. MVLTLs are applied also in Ref. [24], together with moment invariants.

Invariant descriptors can be used as well in situations, when no precedent feature detection was done and the invariants are successively computed for the window sliding across the whole image [55]. For translated and rotated images, Goshtasby [66] proposed to calculate the moment invariants [93] from the circular-shaped windows and then to apply the CC criterion on the moment window representation. A similar idea was used earlier by Wong and Hall [213]. Along with the moment-based window description, they applied hierarchical search strategy to match radar and optical images.

#### 4.2.3. Relaxation methods

A large group of the registration methods is based on the relaxation approach, as one of the solutions to the consistent labeling problem (CLP): to label each feature from the sensed image with the label of a feature from the reference image, so it is consistent with the labeling given to the other

feature pairs [130]. The process of recalculating the pair figures of merit, considering the match quality of the feature pairs and of matching their neighbors, is iteratively repeated until a stable situation is reached. The reference work was done by Ranade and Rosenfeld [148]. Here, the displacement of the feature sets transformed by a certain geometric transformation defines the figures of merit of the feature pairs. This method can handle shifted images and it tolerates local image distortions.

Wang et al. [204] extended the classical relaxation by including the description of the corner features. They used corner sharpness, contrast, and slope. This algorithm allows to handle translation and rotation distortions in the images, but it is computationally demanding. Medioni and Nevatia [128] used line features and their descriptors (coordinates, orientation, average contrast). Cheng and Huang [33] proposed a star-based registration which considers individual feature points along with all links to their neighbors. Ton and Jain [190] speeded up the algorithm by integrating the MergeSort concept. Their method works with shifted and rotated images. Relaxation based method even for similarity transformed images was proposed, for example, by Cheng [32], Ogawa [136] and Li [113]. Different relaxation methods are compared in Ref. [147].

Another solution to the CLP problem and consequently to the image registration is backtracking, where consistent labeling is generated in recursive manner. A registration method based on backtracking is described in Ref. [130].

#### 4.2.4. Pyramids and wavelets

We conclude the discussion about the feature matching by mentioning some works that try to reduce the computational cost due to the large image size by means of pyramidal approach.

First attempts were done back in 1977. Vanderbrug and Rosenfeld concentrated in their work on the amount of computation needed for the window pair testing. In Ref. [197], they used a subwindow first to find probable candidates of the corresponding window in the reference image and then the full-size window was applied. They discussed the appropriate choice of the subwindow size to minimize the expected computational cost. In Ref. [160] they proposed to use first both the sensed and the reference images at a coarser resolution and then, on locations with small error measure, to match higher resolution images. Althof et al. [4] proposed to decrease the necessary computational load by taking just a sparse regular grid of windows for which the cross correlation matching is performed. These techniques are simple examples of pyramidal methods.

In general, this coarse-to-fine hierarchical strategy applies the usual registration methods, but it starts with the reference and sensed images on a coarse resolution (generated using Gaussian pyramids, simple averaging or wavelet transform coefficients, among others). Then they gradually improve the estimates of the correspondence or of

the mapping function parameters while going up to the finer resolutions. At every level, they considerably decrease the search space and thus save the necessary computational time. Another important advantage resides in the fact that the registration with respect to large-scale features is achieved first and then small corrections are made for finer details. On the other hand, this strategy fails if a false match is identified on a coarser level. To overcome this, a backtracking or consistency check should be incorporated into the algorithms.

Combining CC with the pyramidal approach that exploits a summing pyramid (the pixel value at a coarser level corresponds to the summation of the pixel values on the previous level), a median pyramid, and an averaging pyramid was proposed in Refs. [37,208,219], respectively. Wong and Hall [214] combined the SSDA method with pyramidal speed-up. Wang and Chen [205] extracted features (centroids of closed boundary regions) at every resolution level and found the parameters of geometric deformation from the histogram of angle differences and line-length ratios, as mentioned above. Thévenaz et al. applied a cubic spline based pyramid along with the minimization of the mean square intensity difference between the images [184] and the MI maximization [187], respectively. Sharma and Pavel [166] used the multiresolution Laplacian pyramid for the infrared and radar images registration. Kumar et al. [102] combined different types of pyramids (Laplacian, Gaussian) with different similarity measures (CC, sum of squared differences) to register aerial video sequences. Non-linear min-max filters applied in a pyramidal scheme was used in Ref. [169].

Recently, wavelet decomposition of the images was recommended for the pyramidal approach due to its inherent multiresolution character. Methods can differ in the type of the applied wavelet and the set of wavelet coefficients used for finding the correspondence. Most frequently used methods decompose the image recursively into four sets of coefficients (LL, HL, LH, HH) by filtering the image successively with two filters, a low-pass filter L and a high-pass filter H, both working along the image rows and columns.

Turcajova and Kautsky [193] tested various orthogonal and biorthogonal wavelets (they used LL coefficients) together with CC on a regular grid of points to register affine transformed images. Spline biorthogonal wavelets and Haar wavelet outperformed others. Fonseca and Costa [58] detected the modulus maxima of LH and HL coefficients and looked for the maxima of the correlation coefficients, computed from LL coefficients in small surroundings of the detected maxima. Djamdji et al. [41] use just HH coefficients. Le Moigne [105] applied the Daubechies wavelet to register Landsat images and AVHRR data. They extracted LH and HL frequency coefficients and found the correspondence by means of CC. Liu et al. [118] proposed the application of Gabor

wavelet transform and Gaussian model of registration residua. You and Bhattacharya [217] use the maximum compact fuzzy sets of wavelet coefficients as features and HD as similarity measure. The robustness of the registration by means of the Daubechies and Haar wavelets was studied in Ref. [176].

#### 4.2.5. Summary

Area-based methods are preferably applied when the images have not many prominent details and the distinctive information is provided by graylevels/colors rather than by local shapes and structure. Area-based methods have two principal limitations. Reference and sensed images must have somehow 'similar' intensity functions, either identical (and then correlation-like methods can be used) or at least statistically dependent (this typically occurs in multimodal registration).

From the geometric point of view, only shift and small rotation between the images are allowed when using area-based methods (although the area-based methods can be generalized to full rotation and scaling, it is practically meaningless because of an extreme computational load). To speed up the searching, area-based methods often employ pyramidal image representations and sophisticated optimization algorithms to find the maximum of the similarity matrix.

Feature-based matching methods are typically applied when the local structural information is more significant than the information carried by the image intensities. They allow to register images of completely different nature (like aerial photograph and map) and can handle complex between-image distortions. The common drawback of the feature-based methods is that the respective features might be hard to detect and/or unstable in time. The crucial point of all feature-based matching methods is to have discriminative and robust feature descriptors that are invariant to all assumed differences between the images.

## 5. Transform model estimation

After the feature correspondence has been established the mapping function is constructed. It should transform the sensed image to overlay it over the reference one. The correspondence of the CPs from the sensed and reference images together with the fact that the corresponding CP pairs should be as close as possible after the sensed image transformation are employed in the mapping function design.

The task to be solved consists of choosing the type of the mapping function (see Fig. 5) and its parameter estimation. The type of the mapping function should correspond to the assumed geometric deformation of the sensed image, to the method of image acquisition (e.g. scanner dependent distortions and errors) and to the required accuracy of the registration (the analysis of error

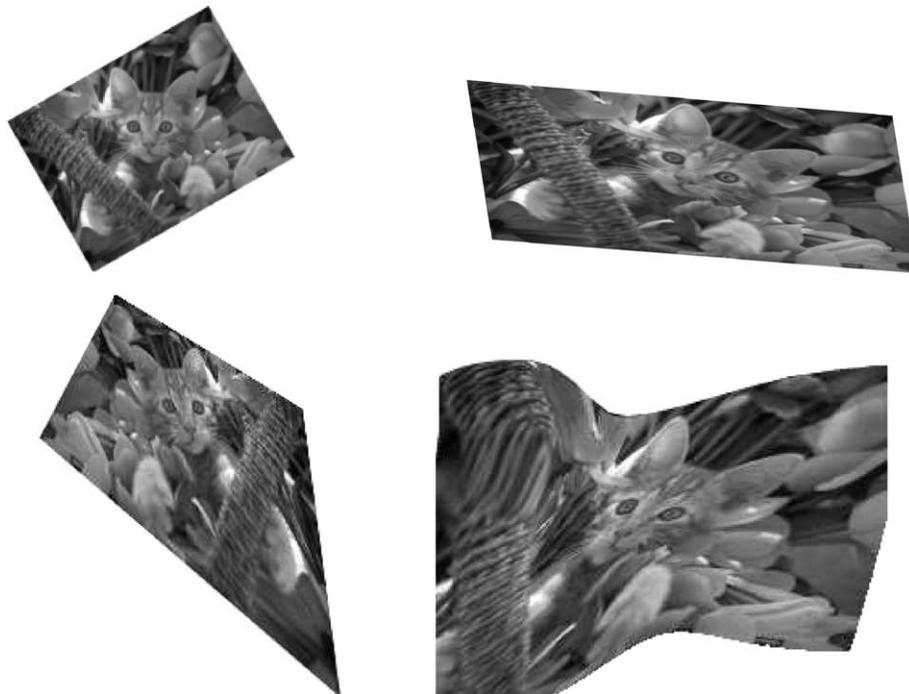

Fig. 5. Examples of various mapping functions: similarity transform (top left), affine transform (top right), perspective projection (bottom left), and elastic transform (bottom right).

for rigid-body point-based registration was introduced in Ref. [48]).

In special situations when the geometric deformation is partially known, e.g. when there exists a model for the distortion caused by the acquisition device and/or the scene geometry, the pre-correction based on the inverse of the deformation can be performed (for example, in Refs. [94,168,181], the authors model the Earth's shape and rotation, the satellite orbit and the scanning geometry of the sensor).

Models of mapping functions can be divided into two broad categories according to the amount of image data they use as their support. Global models use all CPs for estimating one set of the mapping function parameters valid for the entire image. On the other hand, the local mapping functions treat the image as a composition of patches and the function parameters depend on the location of their support in the image. It leads to the tessellation of the image, usually a triangulation, and to the defining of parameters of the mapping function for each patch separately.

From another point of view, mapping functions can be categorized according to the accuracy of overlaying of the CPs used for computation of the parameters. Interpolating functions map the sensed image CPs on the reference image CPs exactly, whereas approximating functions try to find the best trade-off between the accuracy of the final mapping and other requirements imposed on the character of the mapping function. Since the CP coordinates are

usually supposed not to be precise, the approximation model is more common.

### 5.1. Global mapping models

One of the most frequently used global models uses bivariate polynomials of low degrees. Similarity transform is the simplest model—it consists of rotation, translation and scaling only

$$u = s(x \cos(\varphi) - y \sin(\varphi)) + t_x$$

$$v = s(x \sin(\varphi) + y \cos(\varphi)) + t_y$$

This model is often called 'shape-preserving mapping' because it preserves angles and curvatures and is unambiguously determined by two CPs.

Slightly more general but still linear model is an affine transform

$$u = a_0 + a_1x + a_2y$$

$$v = b_0 + b_1x + b_2y,$$

which can map a parallelogram onto a square. This model is defined by three non-collinear CPs, preserves straight lines and straight line parallelism. It can be used for multiview registration assuming the distance of the camera to the scene is large in comparison to the size of the scanned area, the camera is perfect (a pin-hole camera), the scene is flat, and the present geometric distortion has no local factors.

If the condition on the distance of the camera from the scene is not satisfied the perspective projection model

$$u = \frac{a_0 + a_1x + a_2y}{1 + c_1x + c_2y}$$

$$v = \frac{b_0 + b_1x + b_2y}{1 + c_1x + c_2y}$$

should be used. This model exactly describes a deformation of a flat scene photographed by a pin-hole camera the optical axis of which is not perpendicular to the scene. It can map a general quadrangle onto a square while preserving straight lines and is determined by four independent CPs.

Slight violations of these assumptions may lead to the use of the second or the third-order polynomial models. Higher order polynomials usually are not used in practical applications because they may unnecessarily warp the sensed image in areas away from the CPs when aligning with the reference image.

In general, the number of CPs is usually higher than the minimum number required for the determination of the mapping function. The parameters of the mapping functions are then computed by means of the least-square fit, so that the polynomials minimize the sum of squared errors at the CPs. Such mapping functions do not map the CPs onto their counterparts exactly. This approach was proved to be very effective and accurate for satellite images, for instance.

### 5.2. Local mapping models

However, a global polynomial mapping cannot properly handle images deformed locally. This happens, for instance, in medical imaging and in airborne imaging. The least square technique averages out the local geometric distortion equally over the entire image which is not desirable. Local areas of the image should be registered with the available information about the local geometric distortion in mind.

Several authors have shown the superiority of the local or at least locally sensitive registration methods above the global ones in such situations (Goshtasby [69], Ehlers and Fogel [46], Wiemker [209], and Flusser [50], among others). The weighted least square and weighted mean methods [69] gain the ability to register images locally by introducing the slight variation to the original least square method. The local methods called piecewise linear mapping [67] and piecewise cubic mapping [68], together with the Akima's quintic approach [209], apply the combination of the CP-based image triangulation and of the collection of local mapping functions each valid within one triangle. These approaches belong to the group of the interpolating methods.

### 5.3. Mapping by radial basis functions

Radial basis functions are representatives of the group of global mapping methods but they are able to handle even

locally varying geometric distortions. The resulting mapping function has a form of a linear combination of translated radially symmetric function plus a low-degree polynomial

$$u = a_0 + a_1x + a_2y + \sum_{i=1}^N c_i g(\mathbf{x}, \mathbf{x}_i)$$

and similarly for  $v$ .

Originally they were developed for the interpolation of irregular surfaces. Their name 'radial' reflects an important property of the function value at each point-it depends just on the distance of the point from the CPs, not on its particular position. Multiquadrics, reciprocal multiquadrics, Gaussians, Wendland's functions, and thin-plate splines are several examples of the radial basis functions used in image registration.

The application of the multiquadrics in the airborne remote sensing, together with the comparison to the third order polynomial method, is described in Ref. [46]. Its comparison to the Akima's method is presented in Ref. [209]. The medical application of multiquadrics is shown in Ref. [117]. Wendland's functions applied in medical image registration appear in Ref. [60]. These functions have very small global influence and even significant local deformations can be well registered by this approach. This property is advantageous for registering medical images, where changes occur mainly locally.

The most often used representatives of the radial basis functions are the thin-plate splines (TPS), where the radial terms have the form

$$g(\mathbf{x}, \mathbf{x}_i) = \|\mathbf{x} - \mathbf{x}_i\|^2 \ln(\|\mathbf{x} - \mathbf{x}_i\|)$$

(see Duchon [44] and Wahba [203] for the respective mathematical background). Although they had been used in mechanics and engineering for decades [84], they were introduced to image analysis community by Grimson [78] and Bookstein [21]. The TPS can be viewed as a very thin plate, which is fixed at the positions determined by the CPs in the reference image in the heights given by the  $x$  or  $y$  coordinates of the corresponding CPs in the sensed image [70]. The TPS minimizes the quadratic variation functional of potential energy that reflects the amount of function variation and which should be small for a good mapping function. The type of registration can be chosen: exact interpolation [70], approximation [159] or generalized approximation taking into account that the anisotropic landmark errors [157] are possible. A comprehensive study focused on TPS-based registration of medical images can be found in Ref. [156].

The TPS registration gives good results but the computations can be very time consuming, namely if the number of CPs is high. Considerable attention has been paid to the methods decreasing the complexity of the TPS evaluation while preserving reasonable accuracy. Flusser [50] proposed an adaptive approximation of the TPS on

square or triangular regions by simpler functions. Beatson and Newsam [15] adapted an earlier method by Greengard [75] for multipole expansion of radial functions. Powell [144] reduced the computational cost by the TPS tabulation. Barrodale et al. [13] paid attention to fast and robust calculation of the TPS coefficients.

Numerous papers have dealt with the comparison of the performance of thin-plate splines and other mapping functions. In Refs. [57,70,209] they are compared with polynomials and multiquadrics when registering aerial images. The comparison of the TPS with the Gaussian radial basis functions and with multiquadrics considering their local properties was done in Ref. [8]. It was concluded that the TPS have favorable properties when used as mapping functions for image registration, while the other radial basis functions are more convenient for other applications such as image warping and morphing [8].

The TPS are not the only representatives of the spline family used for the mapping function design. A linear combination of translated cubic B-splines was used for the registration of the echo planar images [103]. Another type of spline-based function, the elastic body spline (EBS), was proposed in [39]. It evolved from the description of the equilibrium displacements of homogeneous isotropic elastic material subjected to a load. Body tissues depicted in the image data to be registered often have properties of elastic material. The EBS was used for the registration of 3D MRI images of breasts. The authors claimed the EBS had outperformed the TPS in their experiments.

#### 5.4. Elastic registration

Another approach to the registration of images with considerable complex and/or local distortions is *not* to use any parametric mapping functions, where the estimation of the geometric deformation is reduced to the search for the ‘best’ parameters. This idea were introduced by Bajcsy et al. [10] and is often called *elastic registration*.

The images are viewed as pieces of a rubber sheet, on which external forces stretching the image and internal forces defined by stiffness or smoothness constraints are applied to bring them into alignment with the minimal amount of bending and stretching. The feature matching and mapping function design steps of the registration are done simultaneously. This is one of the advantages of elastic methods, because feature descriptors invariant to complicated deformations are not known and the feature correspondence is difficult to establish in the traditional way. The registration is achieved by locating the minimum energy state in an iterative fashion. A pyramidal approach is often applied. The external forces can be derived from the local optimization of the similarity function which is defined by the intensity values or by the correspondence of boundary structures [38], among others. In Ref. [140], no

external forces were used and the prescribed displacements, derived from the correspondence of boundary structures, were incorporated to the elastic image deformation.

Disadvantage of elastic registration is in situations when image deformations are very localized. This can be handled by means of *fluid registration*. Fluid registration methods make use of the viscous fluid model to control the image transformation. The reference image is here modelled as a thick fluid that flows out to match the sensed image under the control of the derivative of a Gaussian sensor model. This approach is mainly used in medical applications [25]. The weakness of this approach is blurring introduced during the registration process. Lester and Arridge [110] proposed to use fluid model just for finding the correspondence of CPs and then process the very transformation by means of the thin plate splines. Comparison of three methods for fluid-based registration can be found in Ref. [212].

Another examples of non-rigid methods are *diffusion-based registration*, *level sets registration*, and *optical flow based registration*. The diffusion registration handles object contours and other features as membranes, setting the geometrical constraints. Three variations of this approach are described in Ref. [189]. Different solution was proposed by Andersen and Nielsen [5]. Vemuri et al. [199] introduced elastic registration method, based on evolution of level sets, moving along their respective normals. Finally, the optical flow approach was originally motivated by estimation of relative motion between images [19]. The class of optical flow registration covers very large number of methods and is beyond the scope of this survey.

#### 6. Image resampling and transformation

The mapping functions constructed during the previous step are used to transform the sensed image and thus to register the images. The transformation can be realized in a forward or backward manner. Each pixel from the sensed image can be directly transformed using the estimated mapping functions. This approach, called a forward method, is complicated to implement, as it can produce holes and/or overlaps in the output image (due to the discretization and rounding). Hence, the backward approach is usually chosen. The registered image data from the sensed image are determined using the coordinates of the target pixel (the same coordinate system as of the reference image) and the inverse of the estimated mapping function. The image interpolation takes place in the sensed image on the regular grid. In this way neither holes nor overlaps can occur in the output image.

The interpolation itself is usually realized via convolution of the image with an interpolation kernel. An optimal interpolant—2D *sinc* function—is hard to implement in practice because of its infinite extent. Thus, many simpler interpolants of bounded support have been investigated in the literature. In order to reduce the computational cost,

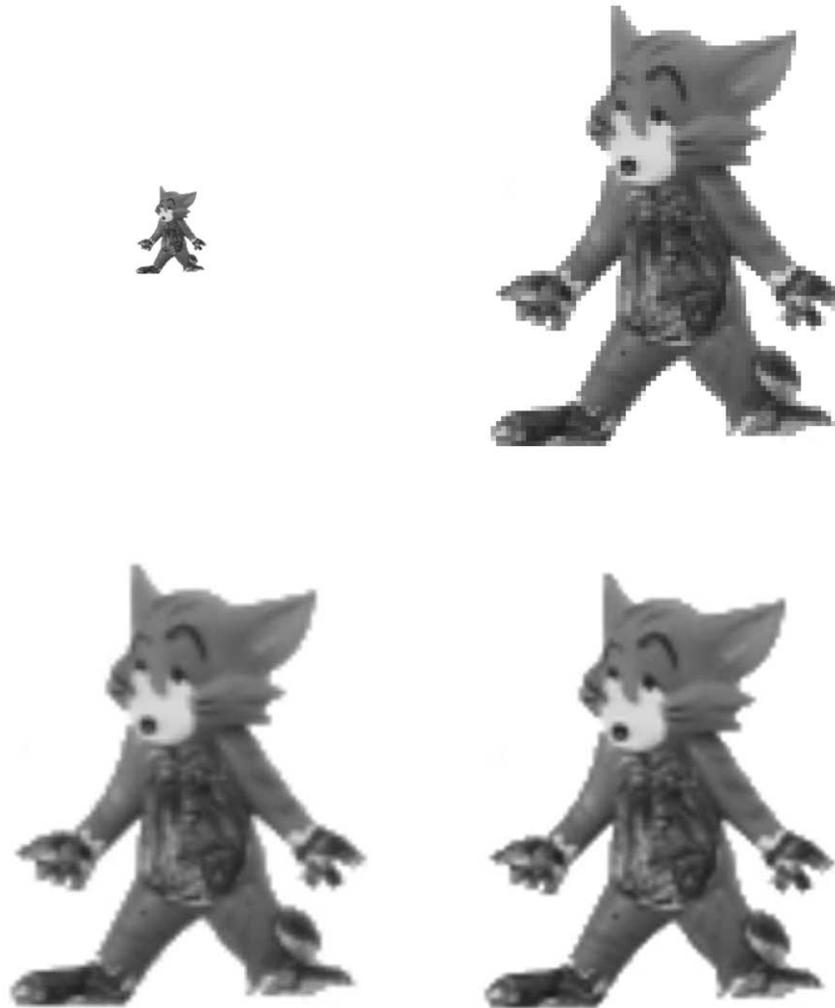

Fig. 6. Image interpolation methods: the original image (top left) was enlarged five times using three different interpolation techniques—nearest neighbor (top right), bilinear (bottom left), and bicubic (bottom right).

preferably separable interpolants have been considered. The separability enables to replace an  $m \times m$  2D convolution by  $(m + 1)$  1D convolutions which is much faster.

The nearest neighbor function, the bilinear and bicubic functions (see Fig. 6), quadratic splines [42,191], cubic B-splines [89], higher-order B-splines [108], Catmull–Rom cardinal splines [100,184], Gaussians [7], and truncated sinc functions [182] belong to the most commonly used interpolants. Meijering et al. [129] investigated higher-order polynomial kernels (quintic and septic). However, their experiments showed only marginal improvement in comparison with cubic interpolation at an highly increased computational cost.

Several survey papers on resampling techniques have been published in the last years. A detailed investigation and comparison of methods was carried out in Ref. [138] for 2D images and in Ref. [76] for 3D data. Thevenaz et al. [182] paid attention to the elimination of undesired interpolation artifacts. Lehman et al. [109] published a survey article covering main interpolation methods (various versions of

*sinc* functions, nearest neighbor, linear, quadratic, cubic, cubic B-spline, Lagrange and Gaussian kernels) with the emphasis on medical imaging applications. They compared them using the spatial and Fourier analysis and tested the computational complexity as well as interpolation errors. Most recently, Thevenaz et al. [183] have proposed a different approach to image resampling. Unlike the other methods, their resampling functions do not necessarily interpolate the image graylevels. They rather interpolate values calculated as certain functions of the graylevels. The authors have demonstrated this approach outperforms traditional interpolation techniques.

Even though the bilinear interpolation is outperformed by higher-order methods in terms of accuracy and visual appearance of the transformed image, it offers probably the best trade-off between accuracy and computational complexity and thus it is the most commonly used approach. Cubic interpolation is recommended when the geometric transformation involves a significant enlargement of the sensed image. Nearest neighbor interpolation should be

avoided in most cases because of artifacts in the resampled image. The only exclusion is when the image to be transformed contains low number of intensities and we do not want to introduce ‘synthetic’ graylevels/colors by higher order interpolation.

## 7. Evaluation of the image registration accuracy

Regardless of the particular images, the used registration method, and the application area, it is highly desirable to provide the user with an estimate how accurate the registration actually is. The accuracy evaluation is a non-trivial problem, partially because the errors can be dragged into the registration process in each of its stages and partially because it is hard to distinguish between registration inaccuracies and actual physical differences in the image contents. In this Section, we review basic error classes and methods for measuring the registration accuracy.

*Localization error.* Displacement of the CP coordinates due to their inaccurate detection is called localization error. Being an intrinsic error of the detection method, the localization error cannot be measured directly on the given image. However, the mean precision of most CP detection methods is known for various image types from computer simulation studies and ground truth comparisons. This can be used for estimation of the expected localization error in the particular case. Localization error can be reduced by selecting an ‘optimal’ feature detection algorithm for the given data but usually there is a trade-off between the number of detected CP candidates and the mean localization error. Sometimes we prefer to have more CP with higher localization error rather than only few of them, yet detected more precisely.

*Matching error.* Matching error is measured by the number of false matches when establishing the correspondence between CP candidates. It is a serious mistake which usually leads to failure of the registration process and should be avoided. Fortunately, in most cases it can be ensured by robust matching algorithms. False match can be identified by consistency check, where two different matching methods are applied to the same set of the CP candidates. Only those pairs found by the both methods are considered as valid CP pairs, the other candidate points are excluded from the further processing. In case there is no other reliable matching method, false CP pairs can be identified by cross-validation. In each step, we exclude one pair from the set of CP’s and calculate the mapping parameters (translation vector and rotation angle for instance). Then we check how well the excluded points are mapped one to the other by this model. If their displacement is below a given threshold, they are accepted as a valid CP pair.

*Alignment error.* By the term alignment error we denote the difference between the mapping model used for the registration and the actual between-image geometric

distortion. Alignment error is always present in practice because of two different reasons. The type of the chosen mapping model may not correspond to the actual distortion and/or the parameters of the model were not calculated precisely. The former case is caused by lack of a priori information about the geometric distortion while the latter originates from the insufficient number of CP’s and/or their localization errors.

Alignment error can be evaluated in several ways. The simplest measure is a mean square error at the CP’s (CPE). Although commonly used, it is not good alignment error measure. In fact, it only quantifies how well the CP coordinates can be fitted by the chosen mapping model. For any CP set, zero CPE can be reached just by selection of a mapping model with enough degrees of freedom (this well-known phenomenon is in numerical analysis called ‘overfitting’). On the other hand, large CPE can be caused by CP localization errors and does not necessarily reflect poor registration accuracy.

Very similar to the CPE is so called test point error (TPE). Test points are CPs that were deliberately excluded from the calculation of the mapping parameters. TPE cannot be set to zero by overfitting which makes it more meaningful than CPE. However, the localization error of the test points may negatively affect this measure. This method can be used only if a sufficient number of the CP’s is available. Otherwise, the exclusion of several CP’s may result in inaccurate estimation of mapping parameters. In medical applications, CP’s can be far from the region of interest. Thus, Fitzpatrick et al. [47,49] proposed to detect anatomical points within the region of interest and to use them as test points (the called them ‘target points’). The concept of TPE can be extended such that the distance between corresponding ‘test’ lines or surfaces is measured [134,139].

Another approach to estimation of alignment accuracy is consistency check using multiple cues. Here, the image registered by the method under investigation is compared (by a proper metric in the image space) with the same image registered by another comparative method. As the comparative method we use preferably ‘gold standard method’, which is a method commonly believed to be the best in the particular application area or for the given image type (gold standard method then plays a role similar to ground truth). This approach is often used in medical imaging [47,207]. In application areas where any gold standard does not exist, like in remote sensing, computer vision, and industrial inspection, we take as the comparative method any method of different nature. Small difference between the registration results then indicates (although does not guarantee) good registration accuracy.

Different consistency check can be employed when a set of at least two sensed images is registered to the same reference [34,63,87,215]. The sensed images can be also registered among themselves using the same set of CP’s, which provides another set of mapping parameters. Using

transitivity of mappings, we obtain for each sensed image two sets of mapping parameters, i.e. two registered images, which should be theoretically the same. The displacement of the test points can serve as a quality measure.

Finally, the oldest method of registration accuracy estimation—visual assessment by a domain expert—should be mentioned. It is still in use at least as a complement of the above mentioned objective error measures.

Estimation of accuracy of registration algorithms is an substantial part of registration process. Without quantitative evaluation, no registration method can be accepted for practical utilization. A lot of work has been done on validation of rigid-body registration (the most comprehensive case-study is probably the Vanderbilt University project [207]) while validation of non-linear, local and elastic registration methods is still at the beginning.

## 8. Current trends and outlook for the future

Image registration is one of the most important tasks when integrating and analyzing information from various sources. It is a key stage in image fusion, change detection, super-resolution imaging, and in building image information systems, among others. This paper gives a survey of the classical and up-to-date registration methods, classifying them according to their nature as well as according to the four major registration steps. Although a lot of work has been done, automatic image registration still remains an open problem. Registration of images with complex non-linear and local distortions, multimodal registration, and registration of  $N$ -D images (where  $N > 2$ ) belong to the most challenging tasks at this moment.

When registering images with non-linear, locally dependent geometric distortions, we are faced with two basic problems—how to match the CPs and what mapping functions to use for registration. While the second one can be solved at least on theoretical level by using appropriate radial basis functions, the first problem is generally unsolvable due to its nature. Since the between-image deformations can be arbitrary, we cannot use any automatic matching method. Another conceptual question here is how can we distinguish between image deformations and real changes of the scene.

In multimodal registration, MI technique has become a standard reference, mainly in medical imaging. However, being an area-based technique, the MI has principal limitations. To overcome them, some authors combined the MI with other, preferably feature-based, methods to gain higher robustness and reliability. To speed up the computation, they often employed pyramidal image representation along with fast optimization algorithms. Unfortunately, when the images have significant rotation and/or scaling differences, these methods either fail or become extremely time expensive. The future development on this field could pay more attention to the feature-based methods, where

appropriate invariant and modality-insensitive features can provide good platform for the registration. Besides, we trust that new application-specific methods utilizing particular sensor characteristics appear soon in remote sensing.

The major difficulty of  $N$ -D image registration resides in its computational complexity. Although the speed of computers has been growing, the need to decrease the computational time of methods persists. The complexity of methods as well as the size of data still grows (the higher resolution, higher dimensionality, larger size of scanned areas). Moreover, the demand for higher robustness and accuracy of the registration usually enforces solutions utilizing the iterations or backtracking, which also produces increase of computational complexity of the method.

In the future, the idea of an ultimate registration method, able to recognize the type of given task and to decide by itself about the most appropriate solution, can motivate the development of expert systems. They will be based on the combination of various approaches, looking for consensus of particular results.
